

Nesting of COSMO and WRF into various global models - a comparative case study analysis

COSMO-User Seminar
07.03.2013

Sebastian Knist
(Prof. A. Bott)

Usual nesting

global model

local model

boundary conditions

initial values

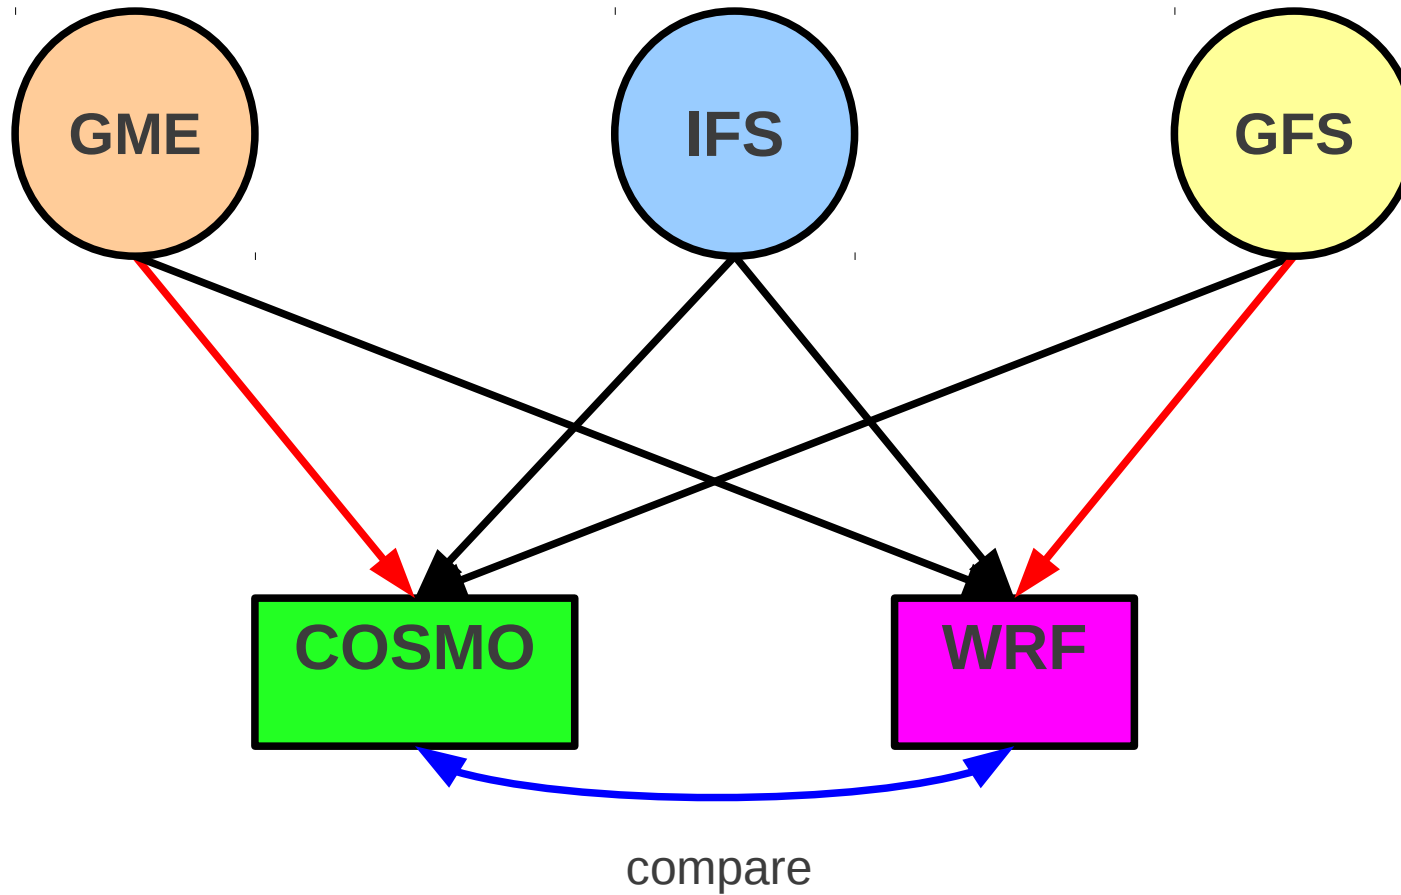

boundary conditions

initial values

Various model nesting

→ 6 possible combinations

Technical challenges

- Different global model grid structures, data format, parameters, parameter ids, etc.

GME

triangular
~30km

60 levels

GFS

lat-lon
0.5°

26 p-levels

- **Preprocessing:**

WRF: **WPS** optional for GFS and IFS data,
for GME first interpolation on lat-lon grid

COSMO: **INT2LM** optional GME and IFS data,
for GFS (GRIB2 format) some additions to the **int2lm_1.18**
(reading of humidity, interpolation of soil variables)

Lateral boundary conditions

- For **real** cases: special lateral boundary conditions supplied by coarser model
- Problem: non-unique information transfer between the models at the boundary due to different spatial resolution and model equations, wave reflexion and numerical noise

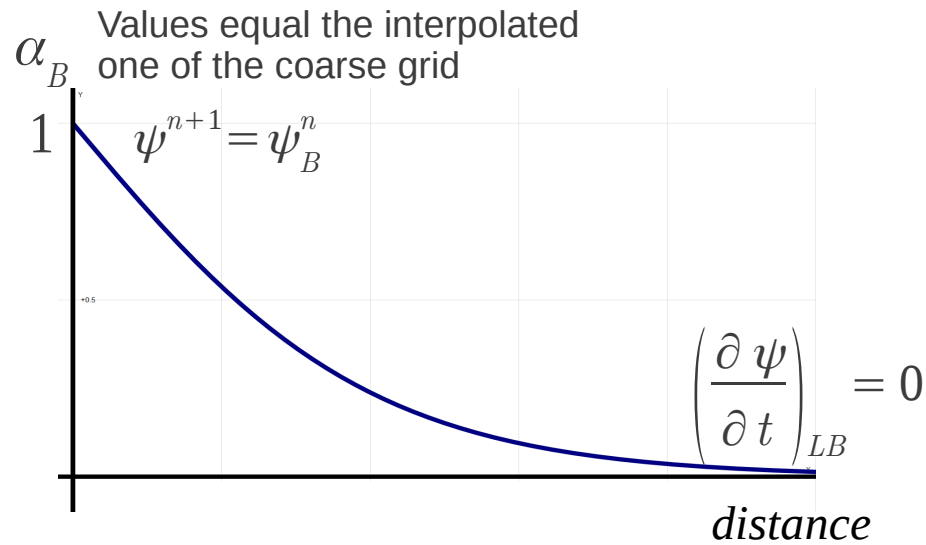

- **Relaxation zone** at the boundary:

COSMO and WRF use **Davies-type** LBC

- additional **lateral forcing term** in the progn. equations, which is active only in the relaxation zone:

$$\left(\frac{\partial \psi}{\partial t}\right)_{LB} = -\mu_B(\psi - \psi_B), \quad \psi^{n+1} = \psi^n - \alpha_B(\psi^n - \psi_B^n), \quad \alpha_B = \frac{\Delta t \mu_B}{1 + \Delta t \mu_B}$$

Lateral boundary conditions

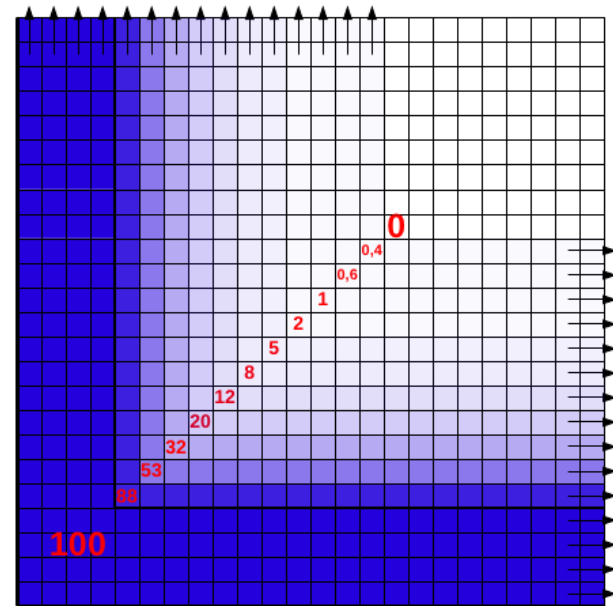

No influence of the boundary

$$\psi^{n+1} = \psi^n - \alpha_B (\psi^n - \psi_B^n)$$

Attenuation coeff.:

$$\alpha_B(d) = \exp(-\gamma d/L)$$

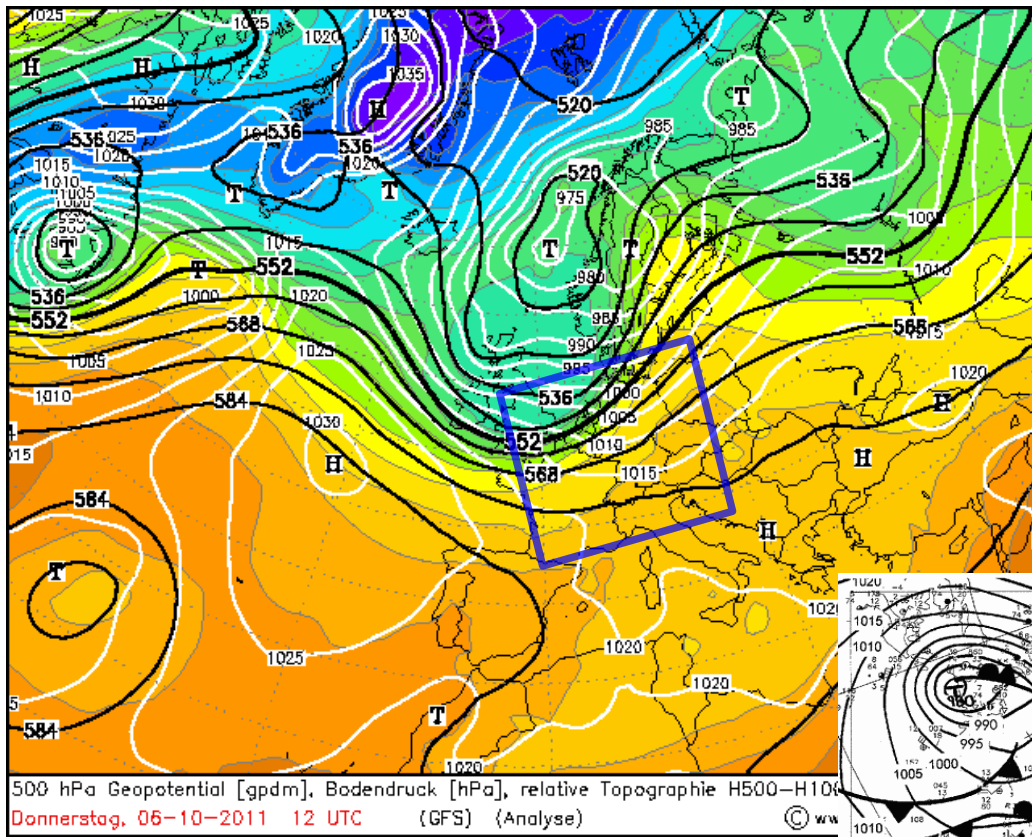

COSMO relaxation zone

Comparison of the 6 model combinations

- Modelling different distinctive synoptic situations
- Qualitative analysis based on characteristic parameters
- How successful is the transformation of the synoptic structure from the lateral boundary to the interior of the local model domain?
- How compatible is the different global model data with each of the local models?
- What differences arise for WRF and COSMO?

- Analysis data: GFS (0.5°, 6h), IFS (0.5°, 6h), GME (~30km, 3h)
- WRF and COSMO same model domain, 200x200x40 GP, 7km resolution, Kain-Fritsch convection, relaxation zone 85km

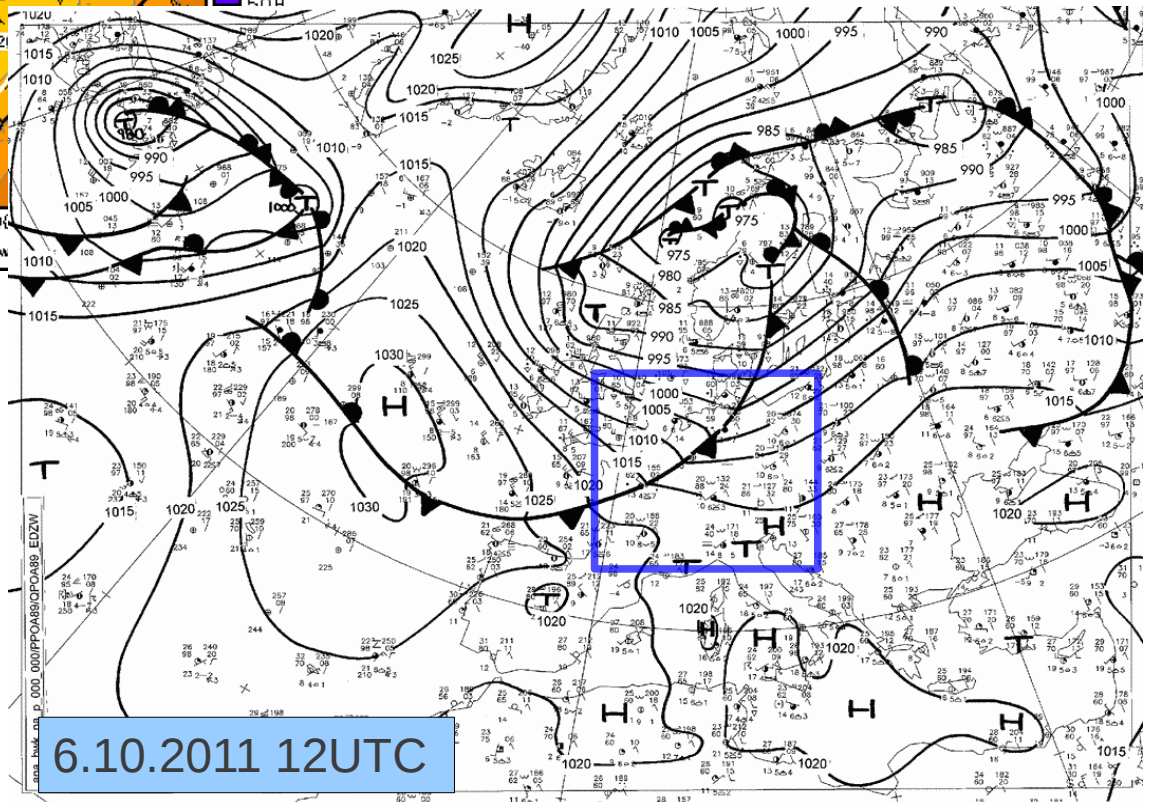

Model test runs of the 6 model combinations

Synoptic situation:

cold front

5.10.2011 12UTC – 7.10.2011 00UTC

- cf passes model domain from NW to SE
- Driving low pressure system outside the model domain

5.10.2011 12UTC + 15h

Effect of linear temporal interpolation at the lateral boundary

- Data of coarse grid available at times every 3 or 6 hours
 - **temporal linear interpolation** for every timestep n:

$$\psi_B^n = \psi_B(T_N) + \frac{\psi_B(T_{N+1}) - \psi_B(T_N)}{\Delta T} (n \Delta t - T_N)$$

Effect of linear temporal interpolation at the lateral boundary

- Data of coarse grid available at times every 3 or 6 hours
 - **temporal linear interpolation** for every timestep n:

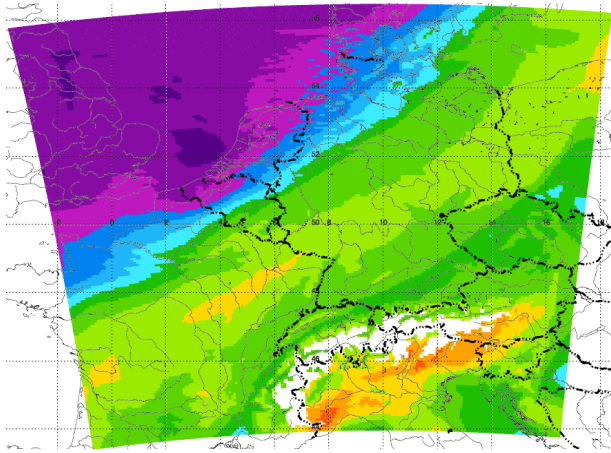

$$\psi_B^n = \psi_B(T_N) + \frac{\psi_B(T_{N+1}) - \psi_B(T_N)}{\Delta T} (n\Delta t - T_N)$$

Conclusions

- Mostly consistent simulation of the synoptic situations with observations in the interior of the local model domain
- Less a coarse spatial interpolation than a coarse temporal interpolation leads to bad manipulation of boundary data
- Similarities for model runs with each the same global model input data
- Differences between COSMO and WRF, especially in precipitation pattern
- Intensive *grid scale* precipitation in the COSMO relaxation zone, especially with GFS input, probably multiple reasons

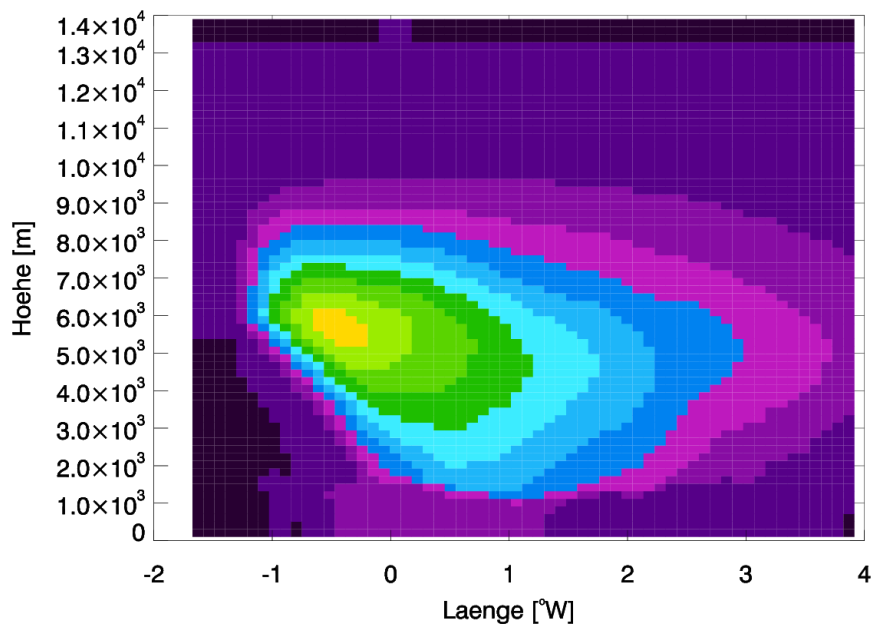

Outlook

- Investigation and improvement of the unrealistic intensive precipitation in COSMO relaxation zone
- More tests for other, less distinctive synoptic situations
- Statistical validation of the six different model combinations

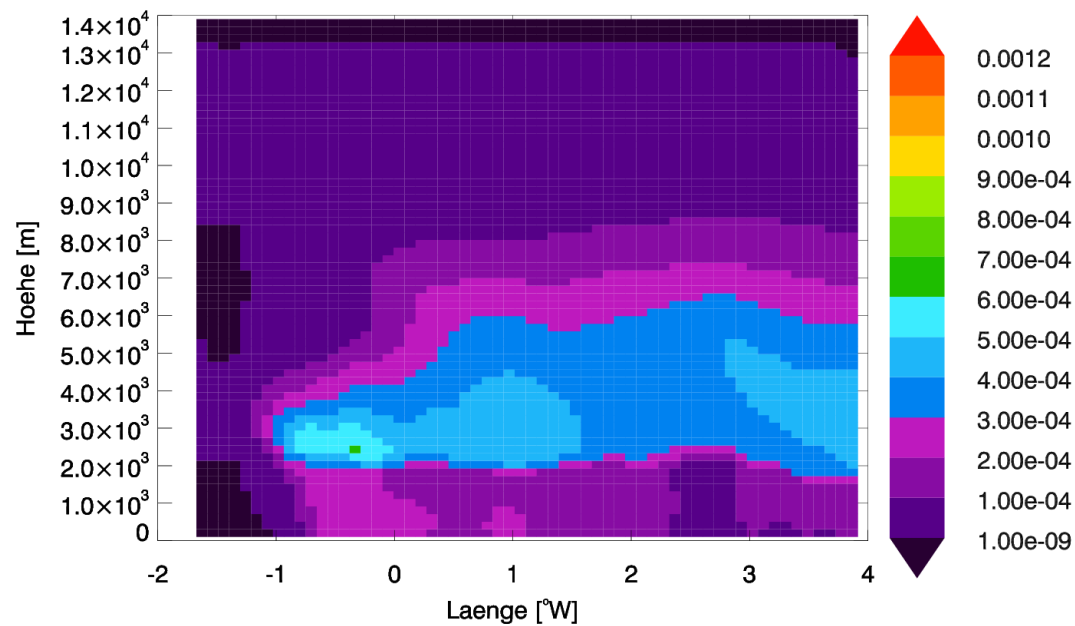

Thank you
for your attention!
